Analyzing the health status of the population using ordinal data

Maria Livia ŞTEFĂNESCU
Research Institute for Quality of Life Romanian Academy

Abstract
We intend to estimate the health status of the people using a Gini kind index GO for measuring the inequality and a polarization indicator PO too. The both indices were applied for ordinal health data which were selected from three national representative samplings designed in the period 2003-2010 in Romania. The results evaluate the evolution level of the polarization and inequality phenomena in the health domain.

Keywords: ordinal data, polarization and inequality indices, health status, SAH data

JEL classification : I14, I19, C43, C19

1. Introduction
The data in health domain are accessible under different forms. We mention here the nominal, ordinal and cardinal (for interval scale) health data. Obviously, the indices which are used to evaluate health status of the individuals or of the nations must be highly associated with the specific kind of data.

Our research is based on three national representative Romanian sampling surveys designed in the years 2003, 2006 and 2010. In the following we intend to analyze the response at the question Q1: “How do you evaluate your status of health”. The question Q1 was addressed to all the persons belonging to the selected samplings. At this question we specified five possibilities of answer, that is: very bad (code 1), bad (code 2), satisfactory (code 3), good (code 4), very good (code 5).

In this context the people answers concerning the subjective self-assessment of the Romanian health status are ordinal data. More precisely, we identify practically five categories $C_1 - C_5$ characterized by the answer codes 1-5. The individuals from a group $C_k$ have often more difficulties concerning their health status in contrast with the persons belonging to the superior groups as $C_{k+1}, C_{k+2}$, etc.

Effectively, the primary data are characterized by the frequencies $f_k$, $1 \leq k \leq m$, where the natural number $f_k$, $f_k \in N$, represents the frequency to have individuals in the category $C_k$ from the specified sampling. Shortly, we will designate by $\bar{f}$ the vector which includes all the frequencies $f_k$, $1 \leq k \leq m$, that is $\bar{f} = (f_1, f_2, f_3, ..., f_m)$.

To simplify our presentation, we will use the notation $f_{k,+}$, $1 \leq k \leq m$, to designate the following expression

$$f_{k,+} = f_1 + f_2 + f_3 + ... + f_k, \ 1 \leq k \leq m$$

(1.1)

The size $n$ of the sampling is just $f_{m,+}$.

More, by $\Delta_{mn}$ we understand the subdomain of $N^m$ having the form

$$\Delta_{m,n} = \{ \bar{f} \mid \bar{f} = (f_1, f_2, f_3, ..., f_m), f \in N^m, f_1 + f_2 + f_3 + ... + f_m = n \}$$

(1.2)

In the subsequent we intend to measure two distinct social phenomena, that is the polarization and also the inequality aspects in health. In practice, the both phenomena are closely related, but we have not a strictly dependence relation between them. More precisely, one of these phenomena can affect in part the other. But for effective real situations this multifaceted relation could have very distinct intensity degrees. A concrete evaluation concerning the inequality and the polarization health levels associated to the years 2003-2010 was given for Romania living in the rural environment.

2. The polarization index $PO$ for SAH data

In the literature, for nominal, ordinal or cardinal types of data, are known a lot of indicators to measure the degree of the polarization phenomenon. These measures depend effectively on the particular type of data. So, for the class of cardinal data we point out the papers: Esteban & Ray (1994), (2012), Duclos & Esteban & Ray (2004), Chakravarty & Majumder (2001), Chakravarty (2009), Rodriguez & Salas (2003), Zhang & Kanbur (2001), Wang & Tsui (2000), Foster & Wolfson (2010), Bossert & Schworm (2008), Deutsch & Silber & Yalonetzky (2013). Some polarization indices were also proposed for categorical data. We remark here the work of Pernamyer & D’Ambrosio (2013). Also we mention especially the following references focused on ordinal data: Apouey (2007), (2010), Montalvo & Reynal-Querol (2005), Apouey & Silber (2013), Kobus (2014), Chakravarty & Maharaj (2012), Makdiisi & Yazbecky (2014).

Strong related with a polarization measure are different indices of variation with could now be applied for ordinal data too. See, for example Berry & Mielke (1992), Blair & Lacy (1996), (2000).

In many recent papers are studied diverse techniques to transform a kind of data in a new type of data. In this context we underline the review of Van Doorslaer & Jones (2003). Therefore, an index used initially for a specific data can be modified to be used for another data types.

Apouey (2007) proposed an one parameter class of polarization indices applied to ordinal SAH (self-assessed health ) data. These types of indices depend on the probabilities of the ordinal categories. In the present paper we will express one of these Apouey polarization indicators in function of the frequency associated to every ordinal class $C_1$ to $C_m$. More precisely, for any $f \in \Delta_{m,n}$ the polarization index $PO$ has the following expression :

$$PO(f) = 1 - \frac{1}{m-1} \sum_{k=1}^{m-1} |2f_{k,1}/n - 1|$$

Apouey (2007) established two main axioms which must be fulfilled compulsory by any polarization index applied to ordinal data. All his proposed indicators satisfy the both axioms and more these indices have good properties to measure the polarization phenomenon in health domain, Apouey (2007), (2010).

It is easy to show by a direct calculus that

**Proposition 2.1.** For any $f \in \Delta_{m,n}$ we have always the inequalities

$$0 \leq PO(f) \leq 1$$

3. An inequality coefficient $GO$ for ordinal data

For an arbitrary ordinal variable $X$ characterized by the frequencies $f$ is not able to operate correctly with the mean $\mu(X)$. Indeed, a score $k$ attached to the ordinal category $C_k$ of $X$ is subjective. These scores $k$ establish only the hierarchy of the classes $C_1$ to $C_m$. More, the value $k$ is not often relevant when is used to characterize all the individuals belonging to the same class $C_k$. Any other set of real values $v_1 < v_2 < v_3 < \ldots < v_m$ could define the weights of the ordered groups $C_k$. $1 \leq k \leq m$.

The methodology to measure the inequality phenomena was intensively developed in the last 50 years. We mention only a bit from this multitude of references : Atkinson (1970), Chakravarty (2009), Duclos & Araar (2006), Haughton & Khandker (2009), Betti & Lemmi (2008), Foster & Seth & Lokshin & Sajaia (2013).

Gini coefficient $G(X)$ is the most popular index to evaluate the degree of inequality for a distribution of cardinal data $X$. This very known indicator was proposed by the famous Italian economist and statistician Corrado Gini at the beginning of the twenty century (Gini (1909a),(1909b)). We remind that Gini index $G(X)$ is based on the Lorenz curve where the mean of the cardinal variable $X$ plays an essential role.

Since the mean $\mu(X)$ of an ordinal variable $X$ has not a clear interpretation we can’t apply correctly the classical Gini coefficient $G(X)$ to measure the inequality from $X$. 

\[ \text{CMSS - VOL. III, ISSUE 1/2015} \]
More indicators were proposed to evaluate inequality aspects in the case of ordinal data. We mention here some references regarding different approaches: Allison R. A., Foster J. E. (2004), Abul & Yalcin (2008), Madden (2010), Giudici & Raffinetti (2011).

Giudici & Raffinetti (2011) adapted the classical Gini coefficient $G(X)$ to any ordinal variable $X$.

More exactly, for all individuals belonging to the class $C_k$ we associate the same rank $r_k$, $1 \leq k \leq m$. But, the rank $r_k$ is modified in function of the ordinal distribution $f$ which is analyzed (Giudici & Raffinetti (2011)). So

$$r_1 = 1, \quad r_k = r_{k-1} + f_{k-1} \text{ for any } 2 \leq k \leq m$$

(3.1)

The ordinal Gini index $GO(f)$ is based on the Lorenz curve defined by the points having the cartesian coordinates $(f_{k,+}/f_{m,+}, q_k/q_m)$, $0 \leq k \leq m$, where

$$q_k = \sum_{j=1}^{k} r_j f_j, \quad 1 \leq k \leq m$$

(3.2)

with the convention $f_{0,+} = q_0 = 0$.

With these notations we define (Giudici & Raffinetti (2011))

$$GO(f) = 1 - \sum_{k=1}^{m} (q_k/q_m + q_{k-1}/q_m)(f_{k,+}/f_{m,+} - f_{k-1,+}/f_{m,+})$$

(3.3)

After a straightforward computations we deduce too

**Proposition 3.1.** For any $f \in \Delta_{m,n}$ the following inequalities are true

$$0 \leq GO(f) \leq 1$$

(3.4)

### 4. Some differences between $PO$ and $GO$ indicators

Therefore, the indicators $PO(f)$ and $GO(f)$ can be used successfully to measure the polarization degree, respectively the inequality level for an arbitrary distribution of frequencies $f$ which characterize an ordinal variable $X$. We established that the both coefficients vary in the interval $[0, 1]$.

But, in practice, between the polarization and the inequality phenomena there is a complex relation of dependence. For this reason, from very closed values of the polarization index $PO$ is possible to often obtain very different values of the inequality coefficient $GO$.

For the subsequent we will prove this assertion taking into consideration the frequency distributions $f$, $f \in \Delta_{3,500}$, of sixteen ordinal variable $X$ precised in Table 4.1.

In **Graphic 4.2** are represented the points $j$, $1 \leq j \leq 16$, having the cartesian coordinates ($PO(X_j)$, $GO(X_j)$), where $X_j$ are the ordinal variables with the frequency distributions $f$ from Table 4.1. The scatter of the points $j$ from **Graphic 4.2** suggests us that there is not a simple dependence relation between the polarization and inequality aspects of the variables $X_j$. More, none of the following inequalities $PO(X) < GO(X)$ or $PO(X) > GO(X)$ are always true for any ordinal variable $X$ (see **Graphic 4.2**).

Having in mind this conclusion, for an accurate interpretation of the health status of a given population, we recommend to use together the two indicators $PO$ and $GO$.

5. An application

We will analyze the evolution of the health status for Romanian living in rural, during the years 2003-2010. In this context we used three representative samplings concerning the quality of life of the Romanian people. The sampling surveys were designed at Research Institute for Quality of Life, Romanian Academy, in the years 2003, 2006 and 2010.

The frequency distributions \( f \) at the question \( Q1 \) where illustrated in Graphic 5.1 together with the associated Lorenz curves obtained after the Giudici & Raffinetti (2011) methodology.

From Graphic 5.1 we remark that the studied distributions and their Lorenz curves are very similar. For this reason is very difficult to evaluate the progress of the Romanian health status in the period 2003-2010.

**Graphic 5.1. The frequency distribution and the Lorenz curve at the question \( Q1 \)**

By applying the polarization \( PO \) and inequality \( GO \) indices to the selected samplings having the volume \( n \) we obtained the values mentioned in Table 5.2. Graphic 5.3 suggests the evolution of the rural Romanian health
status in the period 2003-2010. We remark an easy decreasing of the inequality and an enough consistent increasing of the polarization aspects.

6. Partial conclusions

This proposed methodology, based on the polarization and inequality indices for ordinal data, was applied to evaluate health status for rural Romanian people in the period 2003-2010.

The indices \( PO \) and \( GO \) measure two distinct aspects of the reality, that is the polarization and the inequality phenomena. The two coefficients \( PO \) and \( GO \) vary inside the interval \([0, 1]\). Considering sixteen possible answer distributions we proved that the polarization and inequality situations can be often close related but not identical. In reality, the increase of the polarization level into a community do not compulsory involve the grow of the inequality degree inside that population (see Graphic 4.2). For a precise interpretation of the evolution for the population health status we recommend to use together the both indicators \( PO \) and \( GO \).

For the rural Romanian communities we have a stable decrease of the \( GO \) inequality coefficient in the period 2003-2010. But the behavior of the \( PO \) polarization indicator is different. So, after a light decreasing of the \( PO \) values it results finally an enough consistent increase of the polarization (Graphic 5.3).

To apply correctly our proposed approach is necessary to study the properties of the indices \( PO \) and \( GO \) and in addition, to precise clearly the concrete cases when the both indicators can act in the same direction. It is essential to use more indices to measure distinct aspects of a complex reality. Primary, our option regards an index to identify a positive evolution of a concrete situation. From complementary studies we must also establish some reference distributions considered as equilibrium circumstances for the society.
In the future, using the same kind of processing, we intend to compare the self-assessed health answers at the question $Q_1$ of the people which is divided in more groups. So, the individual health data must be analysed in contrast for different age categories, taking also into consideration the gender of the persons and their domicile, the household income, families with more children, the unemployed people, individuals with disabilities or other deprived groups.
